ABSTRACT

Developing a forensic DNA database on a population that consists of local ethnic groups separated by physical and cultural barriers is questionable as it can be genetically subdivided. On the other side, small sizes of ethnic groups, especially in alpine regions where they are sub-structured further into small villages, prevent collecting a large sample from each ethnic group. For such situations, we suggest to obtain both a total population database on allele frequencies across ethnic groups and a list of θ -values between the groups and the total data. We have genotyped 558 individuals from the native population of South Siberia, consisting of nine ethnic groups, at 17 autosomal STR loci of the kit packages AmpFISTR SGM Plus and AmpFISTR Profiler Plus. The groups differentiate from each other with average θ -values of around 1.1%, and some reach up to three to four percent at certain loci. There exists between-village differentiation as well. Therefore, a database for the population of South Siberia is composed of data on allele frequencies in the pool of ethnic groups and data on θ -values that indicate variation in allele frequencies across the groups. Comparison to additional data on northeastern Asia (the Chukchi and Koryak) shows that differentiation in allele frequencies among small groups that are separated by large geographic distance can be even greater. In contrast, populations of Russians that live in large cities of the European part of Russia are homogeneous in allele frequencies, despite large geographic distance between them, and thus can be described by a database on allele frequencies alone, without any specific information on θ -values.

Population: The DNA database is comprised of allelic frequencies on 558 individuals from South Siberian ethnic groups that patchily dispersed across southern Siberia (Supplementary Fig. S1): 95 Khamnigans, 80 Tuvinians, 80 Altaians-Kizhi, 42 Mongolians, and additional raw genotypic data on 68 Altaians, 78 Buryats, 29 Sojots, 35 Tofalars, and 51 Khakassians described in [1]. Here we use term 'South Siberia' in a geographic context as an area including the Altai-Sayan Mountains, the Lake Baikal region, and northern Mongolia. For the purposes of comparison, we studied a few other Asian populations: 49 Koreans from South Korea and samples from northeastern Asia: 15 Chukchi, 32 Koryaks, and 14 Evens.

As a contrasting example of a homogeneous pattern of population structure, we studied 371 Russians that live in the European part of the Russian Federation: 66 individuals from Belgorod city, 62 from Pskov city, and 59 from Velikiy Novgorod

city; also we used raw genotypic data on 52 individuals from Saratov city, 60 from Mineralnie Vody city, and 72 from Orel city described in [2] (Supplementary Fig. S1). Additionally, we obtained a sample of 13 individuals that have Asian types of mitochondrial DNA (all them belong to macro-haplogroup M) and identified themselves as ethnical Russians. These individuals were from the following cities of the European part of Russia: Kaluga ($n=2$), Pskov ($n=1$), Vladimir ($n=1$), Velikiy Novgorod ($n=2$), Volot ($n=5$), Yaroslavl ($n=1$), and Belgorod ($n=1$). Each population sample comprises unrelated healthy donors from whom appropriate informed consent was obtained.

DNA samples, amplification, genotyping: Blood samples were taken by venipuncture and collected into EDTA vacutainer tubes. DNA was extracted by following the standard phenol-chloroform extraction method. The loci were amplified using PowerPlex[®] 16 System (Promega, Madison, WI) according to manufacturer's instructions. Products of amplification were analyzed using ABI PRISM 3100 Genetic Analyzer (PE Applied Biosystems). All samples were genotyped at loci D18S51, D21S11, TH01, D3S1358, FGA,

TPOX, D8S1179, vWA, CSF1PO, D16S539, D7S820, D13S317, and D5S818. Additionally, the samples collected in this study are typed for loci PentaD and PentaE, whereas those from [1,2] have been typed for D2S1338 and D19S433. Allelic ladders and control DNA samples provided with the kit were used for quality control. GeneScan v. 3.7 and Genotyper v. 3.6 software (PE Applied Biosystems) were used for sizing and genotyping. Allele names are concordant with the recommendations of the DNA Commission of the International Society of Forensic Haemogenetics [3]. GEDNAP and CTS quality control exercises passed successfully by the Forensic Medicine Institute, the Ludwik Rydygier Medical College. The raw genotypic data and allele frequencies in each population sample are presented in [Supplementary Tables A1 and A2](#), respectively; they are available online.

Data analysis: Statistical tests for genetic equilibrium (Hardy–Weinberg's ratios and two-locus linkage equilibrium) and estimates of θ -values were performed with the methods described in [4,5] using software GDA [6]; software SPSS 11.5.0 [7] was applied to principal component analysis.

Results:

A database on the population of South Siberia. The total database for the population of South Siberia provides an exclusion power Q of 0.99999924 across the analyzed 17 loci, with average heterozygosity per a locus of 0.788. Significant deviations from Hardy–Weinberg proportions and linkage equilibrium were found only for vWA (heterozygote excess) and D8S1179/D7S820, with p -values 0.007 and 0.01, respectively, after the Bonferroni correction.

Between-ethnic differentiation in South Siberia. The South Siberian ethnic groups significantly differentiate from each other in allele frequencies, with average θ -value of 0.011 and its 95% bootstrap confidence interval across loci of (0.0090, 0.0131). Since the latter figures do not exceed much the lower level of θ -values suggested by [8], 0.01, we pooled the samples together to obtain a combined reference database on the South Siberian population ([Table 1](#)). To characterize the extent of differentiation of the ethnic groups in allele frequencies, we additionally computed single-locus θ -values between allele frequencies in each ethnic group and those in the combined database ([Table 2](#)).

Table 1

Allele frequencies in the South Siberian population (n is the number of chromosomes examined).

Between-village variation in South Siberia. For four ethnic groups, we extracted data on two major villages in each and found average between-village θ -values to be greatly significant within the Altai-Kizhi and the Tuvian, 0.021 and 0.018, with 95% confidence intervals of (0.0086, 0.0341) and (0.0073, 0.0287), respectively. It is

worth noting that the between-village variation exceeded 0.01 even for those markers that were shown to be least variable between ethnic groups, PentaE,D, D18S51 and D19S433 (Table 2) For other two ethnics, the Khakas and the Altai, the average between-village θ -value was insignificant, but single-locus θ -values exceeded 0.03

Table 2

θ -Values between the allele frequencies in a single ethnic group and those in the combined data on the South Siberian population (from Table 1).

| Loci | Ethnic groups | | | | | | | | | Maximal θ -values |

at loci TPOX, D7S820, D16S539, D2S1338, were higher than 0.01 for D19S433 in the Khakas, and exceeded 0.01 at loci D3S1358, D18S51, and D19S433 in the Altai.

A database on the Russian population. The database provides an exclusion power $Q = 0.999999946$ across the 17 loci, with average heterozygosity per locus $H = 0.795$. Differentiation between Russian samples is insignificant, with average $\theta = 0.0013$ and its 95% confidence interval $(-0.0005, 0.0033)$; the maximal θ -value, 0.010, was found for locus D16S539 only. Therefore, a common database on allele frequencies in European Russians can

be developed by pooling data from the six urban population samples together (Table 3), with no additional information on θ -values.

Between-population differentiation. Differentiation between the South Siberian ethnic groups is high, it increased further when northeastern Asian the Koryak and the Chukchi were added (Supplementary Fig. S2). In contrast, the Russian urban samples are genetically very close to each other, although they are quite distant geographically (Supplementary Fig. S2). Generally, the eastern Slavs seem to be very homogeneous because another Slavic ethnic

group, the Belarusian, is spatially nearly homogeneous across the Republic of Belarus, and differentiation between Russians, Belarusians, and Ukrainians from large cities is very small [9]. It is interesting that a sample of Russians that have Asian types of mitochondrial DNA is close to other Russian samples (Supplementary Fig. S2); this is explained by rapid substitution of autosomal alleles during generations of absorption by the home population.

Other remarks: Some populations are subdivided by natural boundaries into small subpopulations, exemplified by ethnic groups in alpine regions, as well as by social, religious or other kinds of barriers, which makes difficult to establish a forensic database on a single local group as sampling a sufficiently large number of unrelated individuals can be unrealistic. Therefore, pooling data from several neighboring small groups together seems to be the only way to establish a reference database on a subdivided population. On the other hand, such a database may be internally heterogeneous and thus needs to be accompanied by information on variation of allelic frequencies in terms of θ -statistic as it has been suggested in [8]. The value $\theta = 0.03$ has been recommended for use in forensic cases that involve small isolated tribes, such as American Indians, and $\theta = 0.01$ in other cases of subdivision ([8], p. 122). This is appropriate for cases with unknown level of population differentiation. However, when the extent of differentiation can be evaluated from observed data, then using actual estimates of θ -values seems to be more practical especially because actual θ -values in a particular population can greatly vary across loci, thus being for some loci larger than the 0.01 and even may exceed 0.03.

The ethnic groups of the population of South Siberia significantly differentiate from each other in allele frequencies [1]. All these suggest using the allele frequencies from Table 1 together with the maximal θ -values from the very right column of Table 2 in those forensic implications that involve the natives from South Siberia. Moreover, taking in account a possibility of

between-village variation, the θ -values in the right column of Table 2 that are less than 0.01 must be substituted by 0.01 at least.

In contrast, in forensic cases that involve Russians from large cities of European part of Russia (Table 3), θ -values can be taken as 0.01 at most.

The paper is in agreement with the requirements for publication of population data [10].

Acknowledgements

We are grateful to all the voluntary donors of DNA samples used in this study, to Irina Dambueva and Ilia Zakharov for some Siberian samples, and to Sergey Rychkov for some Russian samples. Research supported by grants of The Russian Academy of Sciences “Fundamental Science to Medicine” and “Biodiversity”, and by The Russian Foundation for Basic Research (grants 06-04-48136 and 07-04-00171).
